

# *Neighborhood Effects in Migration Decisions in Rural Mexico\**

Ruben Irvin Rojas Valdes<sup>†</sup>, C.-Y. Cynthia Lin Lawell<sup>‡</sup>, and J. Edward Taylor<sup>§</sup>

## **Abstract**

Given the economic significance of migration and its relevance for policy, it is important to understand the factors that cause people to migrate. We add to the literature on the determinants of migration by examining whether neighborhood effects matter for migration decisions. There are several reasons why a household's migration decisions may depend on the migration decisions of its neighbors, including migration networks and information externalities. Using instrumental variables to address the endogeneity of neighbors' decisions, we empirically examine whether neighborhood effects in migration decisions actually take place in rural Mexico, whether the interactions depend on the size of the village, and whether there are nonlinearities in the neighborhood effects. Our results show that there is a significant and positive own-migration neighborhood effect. In our base case specification, an increase of 0.1 in the fraction of neighbors with migration to the US increases a household's probability of migration to the US by around 5.9 percentage points, while an increase of 0.1 in the fraction of neighbors with migration to other states within Mexico increases a household's probability of migration to other states within Mexico by around 6.3 percentage points. We also find that neighborhood effects vary nonlinearly with village size.

# 1 Introduction

According to estimates from the World Bank (2010a), around 3 percent of the world population lived in a country different from the one in which they were born. The US is the country with the highest immigrant population in the world, with more than 46 million people who were foreign born (United Nations, 2013), of which about 11 million are from Mexico (World Bank, 2010b). These trends are considerably changing demographic portraits, reshaping patterns of consumption, and altering the cultures of both sending and receiving countries.

The economic importance of migration from Mexico to the US is twofold. Since the mid-1980s, migration to the US has represented an employment opportunity for Mexicans during a period of economic instability and increasing inequality in Mexico. In addition, it has represented an important source of income via remittances, especially for rural households (Esquivel and Huerta-Pineda, 2007).<sup>1</sup> Remittances from the US to Mexico amount to 22.8 billion dollars per year, according to estimates from the World Bank (2012). According to recent calculations, an average of 2,115 dollars in remittances is sent by each of the nearly 11 million Mexicans living in the US, which represents up to 2 percent of the Mexican GDP (D’Vera et al., 2013). Some authors estimate that 13 percent of household total income and 16 percent of per capita income in Mexico come from migrant remittances (Taylor et al., 2008).<sup>2</sup>

With a border 3200 kilometers long, the largest migration flow between two countries, and a wage differential for low-skilled workers between the US and Mexico of 5 to 1 (Cornelious and Salehya, 2007), the US-Mexico migration relationship also imposes challenges to policy-makers of both countries. Beginning in 2000, Mexico moved away from its previous so-called ‘no policy policy’, and tried instead to pursue a more active policy to influence the US to agree to a workers program and to increase the number of visas issued for Mexicans, although

---

<sup>1</sup>Esquivel and Huerta-Pineda (2007) find that 3 percent of urban households and up to 10 percent of rural households in Mexico receive remittances.

<sup>2</sup>Castelhana et al. (2016) find that migrant remittances are not associated with increases in rural investment in agricultural production in Mexico, however.

its efforts got frustrated after the 9/11 attacks in September 2001. More recently, other domestic policies have included the programs Paisano and Tres Por Uno, which facilitate the temporary return during holidays of Mexicans legally living in the US and which match the contributions of migrant clubs for the construction of facilities with social impact in Mexican communities, respectively. On the US side, several reforms have been attempted to both open a path for legalization while increasing the expenditure to discourage illegal immigration, both of which affect mostly Mexicans. The most recent, the Deferred Action for Childhood Arrivals, gives access to work permits to individuals who entered the country before they were 16 years of age.

Given the economic significance of migration and its relevance for policy, it is important to understand the factors that cause people to migrate. We add to the literature on the determinants of migration by examining whether neighborhood effects matter for migration decisions. We define 'neighborhood effects' as arising whenever the migration decisions of other households in their village affect a household's payoffs from migration and therefore its decisions to have a member migrate.<sup>3</sup>

There are several reasons why a household's migration decisions may depend on the migration decisions of its neighbors, including migration networks and information externalities. Using instrumental variables to address the endogeneity of neighbors' decisions, we empirically examine whether neighborhood effects in migration decisions actually take place in rural Mexico, whether the interactions depend on the size of the village, and whether there are nonlinearities in the neighborhood effects.

Our results show that there is a significant and positive own-migration neighborhood effect. In our base case specification, an increase of 0.1 in the fraction of neighbors with migration to the US increases a household's probability of migration to the US by around 5.9 percentage points, while an increase of 0.1 in the fraction of neighbors with migration

---

<sup>3</sup>We choose to use the term 'neighborhood effects' instead of 'peer effects' because the term 'peer' often connotes an individual; in contrast; the decision-makers we examine are households rather than individuals. Nevertheless, our concept of 'neighborhood effects' is very similar to that of 'peer effects'.

to other states in Mexico increases a household's probability of migration to other states in Mexico by around 6.3 percentage points. We also find that neighborhood effects vary nonlinearly with village size.

The balance of the paper proceeds as follows. We review the literature in Section 2. In Section 3 we discuss sources of neighborhood effects in migration. Section 4 presents the empirical strategy that allows us to identify the neighborhood effects. Section 5 describes the data. Section 6 presents the empirical results. Section 7 concludes.

## **2 Literature Review**

### **2.1 Determinants of Migration**

The first strand of literature upon which our paper builds is the literature on determinants of migration. The new economics of labor migration posits the household as the relevant unit of analysis. Using the household as the relevant unit of analysis addresses several observed features of migration that are ignored by individualistic models, including the enormous flows of remittances and the existence of extended families which extend beyond national borders. Most applications of the new economics of labor migration assume that the preferences of the household can be represented by an aggregate utility function and that income is pooled and specified by the household budget constraint.

For example, Stark and Bloom (1985) assume that individuals with different preferences and income not only seek to maximize their utility but also act collectively to minimize risks and loosen constraints imposed by imperfections in credit, insurance, and labor markets. This kind of model assumes that there is an informal contract among members of a family in which members work as financial intermediaries in the form of migrants. The household acts collectively to pay the cost of migration by some of its members, and in turn migrants provide credit and liquidity (in form of remittances), and insurance (when the income of migrants is not correlated with the income generating activities of the household). In this

setting, altruism is not a precondition for remittances and cooperation, but it reinforces the implicit contract among household members (Taylor and Martin, 2001). Garlick, Leibbrandt and Levinsohn (2016) provide a framework with which to analyze the economic impact of migration when individuals migrate and households pool income.

In the new economics of labor migration, individual characteristics and human capital variables are also very important because they influence not only the characteristics of the migrants but also the impacts that migration has on the productive activities of the remaining household. Migrants are not homogeneous nor are they a random sample from the population in the host country. Instead, individuals might be selected according to their characteristics and how these characteristics fit in the host country. Positive selection occurs when migrants have (expected) earnings above the mean in both the host and the source economy and negative selection when they would have expected income below the average in both locations. Borjas (1987) presents a variation of the Roy (1951) model which shows that, assuming constant costs, positive selection happens when the variance of the income in the host country is smaller than the variance in the source country, since then it would be as if the source country taxed highly skilled workers and insured less skilled workers. The opposite happens with negative selection.

The importance of migrant characteristics have been analyzed empirically with mixed results. Human capital theory à la Sjaastad (1962) suggests that migrants are younger than those who stay because younger migrants would capture the returns from migration over a longer time horizon. The role of education depends on the characteristics of the host and the source economy. Education is positively related to rural-urban migration but has a negative effect on international migration (Taylor, 1987). The reason is that education is not equally rewarded across different host economies. For example, agricultural work in the United States requires only low-skilled labor, so education has a negative effect on the selection of migrants for this type of work.

Changes in labor demand in the United States has modified the role of migrant char-

acteristics in determining who migrates. Migrants from rural Mexico, once mainly poorly educated men, more recently have included female, married, and better educated individuals relative to the average rural Mexican population (Taylor and Martin, 2001). Borjas (2008) finds evidence that supports the negative selection of Puerto Rico emigrants to the United States, which is consistent with Borjas' (1987) model of negative selection of workers when the source economy has low mean wages and high inequality. On the other hand, Feliciano (2001), Chiquiar and Hanson (2005), Orrenius and Zavodny (2005), McKenzie and Rapoport (2010), Cuecuecha (2005), and Rubalcaba et al. (2008) find that the selection of Mexican migrants occurs from the middle of the wage or education distribution. McKenzie and Rapoport (2007) show that migrants from regions with communities of moderate size in the United States are selected from the middle of the wealth distribution, while migrants from regions with bigger communities in the United States come from the bottom of the wealth distribution.

The financial costs of migration can be considerable relative to the income of the poorest households in Mexico.<sup>4</sup> Migration costs reflect in part the efforts of the host country to impede migration, which might explain why migration flows continue over time and why we do not observe enormous flows of migrants (Hanson, 2010). Migration costs for illegal crossing from Mexico to the United States are estimated to be 2,750 to 3,000 dollars (Mexican Migration Program, 2014). Estimates reported in Hanson (2010) suggest that the cost of the "coyote" increased by 37 percent between 1996-1998 and 2002-2004, mainly due to the increase of border enforcement due to the terrorist attacks of 9/11. Nevertheless, Gathmann (2008) estimates that even when the border enforcement expenditure for the Mexico-United States border almost quadrupled between 1986 and 2004, the increase in expenditure produced an increase the cost of the coyote of only 17 percent, with almost zero effect on coyote demand.

---

<sup>4</sup>Data from the National Council for the Evaluation of the Social Policy in Mexico (CONEVAL) show that the average income of the poorest 20 per cent of rural Mexican households was only 456 dollars a year in 2012.

## 2.2 Strategic interactions among neighbors

In addition to the literature on migration, our paper also builds on the previous literature using reduced-form empirical models to analyze strategic interactions among neighbors. Strategic interactions arise whenever the actions of others affect the payoffs of a decision-maker and therefore the decision-maker's actions. The neighborhood effects we examine in this paper are strategic interactions in which the decision-makers are households in the same village.

We build on the work of Lin (2009), who analyzes the strategic interactions among firms in offshore petroleum production. When individual petroleum-producing firms make their exploration decisions, positive information externalities and negative extraction externalities may lead them to interact strategically with their neighbors. If they do occur, strategic interactions in petroleum production would lead to a loss in both firm profit and government royalty revenue. Lin (2009) examines whether these inefficient strategic interactions take place on U.S. federal lands in the Gulf of Mexico. In particular, she analyzes whether a firm's exploration decisions depend on the decisions of firms owning neighboring tracts of land. To address the endogeneity of neighbors' exploration decisions, she uses variables based on the timing of a neighbor's lease term as instruments for the neighbor's decision. The results suggest that strategic interactions do not actually take place, at least not in exploration, and therefore that the current parameters of the government offshore leasing policy do not lead to inefficient petroleum exploration.

Pfeiffer and Lin (2012) use a unique spatial data set of groundwater users in western Kansas to empirically measure the physical and behavioral effects of groundwater pumping by neighbors on a farmer's groundwater extraction. To address the simultaneity of neighbors's pumping, they use the neighbors' permitted water allocation as an instrument for their pumping.

Robalino and Pfaff (2012) estimate neighbor interactions in deforestation in Costa Rica. To address simultaneity and the presence of spatially correlated unobservables, they instru-

ment for neighbors' deforestation using the slopes of neighbors' and neighbors' neighbors' parcels. They find that neighboring deforestation significantly raises the probability of deforestation. Policies for agricultural development or forest conservation in one area will affect deforestation rates in non-targeted neighboring areas. Similarly, Irwin and Bockstael (2002) investigate strategic interactions among neighbors in land use change using physical attributes of neighboring parcels as instruments to identify the effect of neighbors' behavior.

Morrison and Lin Lawell (2016) investigate the role of social influence in the commute to work. Using instruments to address the endogeneity of commute decisions and a dataset of U.S. military commuters on 100 military bases over the period 2006 to 2013, they show that workplace peers positively influence one another's decisions to drive alone to work and carpool to work.

Topa and Zenou (2015) provide an overview of the research on neighborhoods and social networks and their role in shaping behavior and economic outcomes. They include discussion of empirical and theoretical analyses of the role of neighborhoods and social networks in crime, education, and labor-market outcomes.

Munshi (2003) identifies job networks among Mexican immigrants in the United States labor market. The network of each origin community in Mexico is measured by the proportion of the sampled individuals who are located at the destination (the US) in any year. He uses rainfall in the origin community as an instrument for the size of the network at the destination. Results show that the same individual is more likely to be employed and to hold a higher paying nonagricultural job when his network is exogenously higher.

### **3 Sources of Neighborhood Effects**

In this paper we build upon the literature on the determinants of migration by empirically examining whether neighborhood effects are a determinant of migration decisions as well. We define 'neighborhood effects' as arising whenever the migration decisions of other households

in their village affect a household's payoffs from migration and therefore its decisions to have a member migrate. There are several reasons why households make take into the account the actions of other households in their village when making their migration decisions.

The first source of neighborhood effects are migration networks. Migration networks may affect migration decisions because they may reduce the financial, psychological, and/or informational costs of moving out of the community. Contacts in the source economy lower financial or information costs and reduce the utility loss from living and working away from home. The role of migration networks has been studied by Du, Park and Wang (2005) on China; Bauer and Gang (1998) on Egypt; Battisti, Peri and Romiti (2016) on Germany; Neubecker, Smolka and Steinbacher (forthcoming) on Spain; Alcosta (2011) on El Salvador; Alcala et al. (2014) on Bolivia; Calero, Bedi and Sparro (2009) on Ecauado; Acosta et al. (2008) on Latin America; and several others on Mexico, including Massey and Espinosa (1997) and Massey, Goldring and Durand (1994). These papers find a positive effect of migration networks on the probability of migration. In his analysis of job networks among Mexican immigrants in the U.S. labor market, Munshi (2003) finds that the same individual is more likely to be employed and to hold a higher paying nonagricultural job when his network is exogenously higher. Orrenius and Zavodny (2005) show that the probability of migrating for young males in Mexico increases when their father or siblings have already migrated. McKenzie and Rapoport (2010) find that the average schooling of migrants from Mexican communities with a larger presence in the United States is lower. Networks and the presence of relatives or friends in the host country are consistently found to be significant in studies such as those of Greenwood (1971) and Nelson (1976), among others.

Wahba and Zenou (2005) develop a theoretical model in which individuals are embedded within a network of social relationships. They show that, conditional on being employed, the probability of finding a job through social networks, relative to other search methods, increases and is concave with the size of the network. The effects are stronger for the uneducated. There is however a critical size of the network above which this probability

decreases. They then test empirically these theoretical findings for Egypt using the 1998 Labor Market Survey. The empirical evidence supports the predictions of their theoretical model.

A second source of neighborhood effects are information externalities between households in the same village that may have a positive effect on migration decisions. When a household decides to send a migrant outside the village, other households in the village may benefit from learning information from their neighbor. This information may include information about the benefits and costs of migration, as well as information that enables a household to increase the benefits and reduce the costs of migration.

A third source of neighborhood effects may be relative deprivation (Stark and Taylor, 1989; Stark and Taylor, 1991). Models of relative deprivation consider that a household's utility is a function of its relative position in the wealth distribution of all the households in the community. Individuals who migrate remain attached to their household and remit in order to improve the position of their household with respect the reference group. For this concept to be a valid motive for migration, the migrants must still consider their source country as their reference group, which is likely to happen when the source and the host countries are very different, so migrants do not choose the host country as a reference group. The relative deprivation motive also helps to explain why local migration is different from international migration because when a migrant moves within the same country it is more likely that she changes her relative group since it is easier to adapt in the host economy (where maybe the same language is spoken and the cultural differences are not as dramatic as in the case of international migration). Also, the relative deprivation concept would predict that those individuals from a household that is relatively deprived might decide to engage in international migration rather than domestic migration even though the former is more costly because by migrating locally her position in the most likely new reference group would be even worse than the position she would have if she did not migrate.

Taylor (1987) and Stark and Taylor (1989) empirically test the relative deprivation hy-

pothesis controlling for the household relative position in the village's wealth distribution in Mexico. The results show that relative deprivation increases the probability of migration to the United States, but has no effect on internal migration, which supports the idea that when it is easy to change the reference group, migration might not occur if the position within the new reference group would be worse than the position in the original distribution.

Some behavioral explanations may add to our understanding of social comparisons and reference group formation that explain, for example, the relative deprivation hypothesis. McDonald et al. (2013) use a controlled experiment in which people play a modification of a three-player ultimatum game in which one of the players is given an exogenous amount of money that the other two consider as the reference "group". They show that differences in the wealth level of the reference player matters for the bargaining process in the game because it varies the level of payoff to which players might consider to be entitled.

A fourth source of neighborhood effects is risk sharing. Chen, Szolnoki and Perc (2012) argue that migration can occur in a setting when individuals share collective risk. Each individual in a group decides her amount of contribution for a collective good. If the amount required for the transformation of the private good into the public good is not achieved, all the contributions are lost with a certain probability. They use computer simulations on a grid with randomly seeded "players" who follow simple behavior rules for learning and moving all over the grid. They analyze the emerging patterns after several simulations and find evidence for risk-driven migration, whereby individuals move to another location when the perceived risk of not attaining the amount needed for the public good is higher. Their simulations also show that migration might also promote cooperation, creating spatially diluted groups of "cooperators" who prevent the group from being invaded by free-riders ("defectors"). In a similar fashion, Cheng et al. (2011) use simulations to study the behavior that arises when migration is positively related to wealth. They use a grid to simulate an evolutionary prisoner's dilemma which determines the mobility of players across the grid according to simple behavioral rules. They show that migration might promote cooperation

in the prisoner’s dilemma game. Lin et al. (2011) use a grid and an evolutionary prisoner’s dilemma game in which migration is determined by aspirations, defined as a threshold payoff level of a selected neighbor. Migration occurs with a certain probability if the aspired level of payoffs is greater than the own payoff. They show that aspirations also promote cooperation in the prisoner’s dilemma game. Morten (2016) develops a dynamic model to understand the joint determination of migration and endogenous temporary migration in rural India, and finds that improving access to risk sharing reduces migration.

A fifth source of neighborhood effects is a negative competition effect whereby the benefits of migrating to the US or within Mexico would be reduced if others from the same village also migrate to the US or within Mexico. We hypothesize that negative competition effects are less likely to explain neighborhood effects in migration decisions to the US, however, since the labor market in the US is large relative to the number of migrants from a particular village. Our empirical analysis enables us to examine this hypothesis.

Owing to migration networks, information externalities, relative deprivation, risk sharing, and competition effects, households may take into account the migration decisions of neighboring households when making their migration decisions. Our empirical model is general enough to capture multiple possible sources of neighborhood effects, and enables us to analyze their net effect.

## 4 Empirical Strategy

We estimate reduced-form models of a household’s decision to have a member migrate to the US, and also of its decision to have a member migrate within Mexico. In particular, our dependent variable  $y_{ikt}$  is an indicator variable of whether household  $i$  has migration of type  $k \in [USA, Mexico]$  at time  $t$ , which is equal to 1 for household  $i$  in year  $t$  if a household has a member who is a migrant to/within  $k$  in year  $t$ .

To analyze neighborhood effects in migration, we analyze whether the fraction of neigh-

bors who engage in migration to the US and the fraction of neighbors who engage in migration within Mexico affect a household’s decision to have a member migrate to the US and/or a household’s decision to have a member migrate within Mexico. In particular, we regress household  $i$ ’s decision  $y_{ikt}$  to engage in migration on the fraction  $s_{ikt}$  of the sampled households in the same village as household  $i$ , excluding  $i$ , that engage in migration of type  $k$ .

We estimate the following econometric model:

$$y_{ikt} = \alpha + \sum_k \beta_{sk} s_{ikt} + x'_{it} \beta_x + \mu_i + \tau_t + \varepsilon_{ikt}, \quad (1)$$

where the vector  $x_{it}$  includes covariates at the household, village, municipality, state, and national level as well as border crossing variables;  $\mu_i$  is a village fixed effect; and  $\tau_t$  is a year effect. We also run a set of specifications using a time trend instead of year effects.

The regressors at the household level in  $x_{it}$  include the number of males in the household, the age of the household head; the schooling of the household head; the maximum level of schooling achieved by any of the household members; the average level of schooling, measured as the number of years of education that have been completed, of household members 15 years old and above; a dummy if the household’s first born was a male; the area of land owned by the household that is irrigated for agricultural purposes, interacted with village precipitation; the lagged fraction of household members working in the US; and the lagged fraction of household members working within Mexico.

The regressors at the municipality level in  $x_{it}$  include the number of schools in the basic system, the number of schools in the indigenous system, the number of cars, and the number of buses. The state-level variables in  $x_{it}$  include employment by sector. The national variables in  $x_{it}$  are aggregate variables that represent the broad state of the institutional and economic environment relevant for migration, including the average hourly wage, and wage by sector.

The border crossing variables in  $x_{it}$  includes variables that measure crime, deaths, and border enforcement at nearby border crossing points.

Measuring neighbors' effects is difficult owing to two sources of endogeneity. One source is the simultaneity of the neighborhood effect: if household  $i$  is affected by its neighbor  $j$ , then household  $j$  is affected by its neighbor  $i$ . The other arises from spatially correlated unobservable variables (Manski, 1993; Manski, 1995; Brock and Durlauf, 2001; Conley and Topa, 2002; Glaeser, Sacerdote and Scheinkman, 1996; Moffitt, 2001; Lin, 2009; Robalino and Pfaff, 2012; Pfeiffer and Lin, 2012). It is therefore important to address these endogeneity problems in order to identify any neighborhood effects.

To address the endogeneity of neighbors' migration decisions  $s_{ikt}$ , we use instruments for the fraction of neighbors that engage in migration that are correlated the neighbors' migration decisions but do not affect a household's own-migration decision except through their effect on the neighbors' migration decisions.<sup>5</sup>

One instrument we use for the fraction of neighbors that engage in migration is the neighbors' average number of males in the household, which we define as the average number of males in the household of other households in the same village as  $i$ , but not including  $i$ , at time  $t$ . The idea behind this instrument is that households that differ in the number of male members may have different strategies regarding migration and local work. The average number of males in the families of neighboring households  $j$  is a good instrument because it is likely to affect the migration decisions of neighboring households  $j$ , but it does not affect the decisions of household  $i$  except through its effect on the decisions of neighboring households  $j$ .

A second instrument we use for the fraction of neighbors that engage in migration is the fraction of neighbors whose first born is male, which we define as the fraction of other households in the village of  $i$ , not including  $i$ , at time  $t$  in which the first born was a male.

---

<sup>5</sup>Our use of instruments and two-stage least squares estimation also addresses the negative exclusion bias that affects OLS peer effect estimates even when there is randomized peer assignment (Caeyers and Fafchamps, 2016).

The intuition is similar to the previous instrument. Whether the first born was a male is exogenous. The fraction of neighboring households  $j$  in which the first born is a male is a good instrument because it is likely to affect the migration decisions of neighboring households  $j$ , but it does not affect the decisions of household  $i$  except through its effect on the decisions of neighboring households  $j$ .

A third instrument we use for the fraction of neighbors that engage in migration is the neighbors' average household head schooling, which we define as the average of the household head schooling of other households in the village of  $i$ , but not including  $i$ , at time  $t$ . The intuition why this is a good instrument is that the average household head schooling of other households  $j$  may affect the productivity of other households  $j$ , the schooling and employment decisions of its members, and thus their likelihood to migrate, but it does not affect the decisions of household  $i$  except through its effect on the decisions of neighboring households  $j$ .

A fourth instrument we use for the fraction of neighbors that engage in migration is the fraction of neighbors whose household head is the most educated member of the household, which we define as the fraction of other households in the village of  $i$ , but not including  $i$ , at time  $t$  whose household head is the most educated member of the household. The intuition why this is a good instrument is that the fraction of neighbor households  $j$  in which the household head is the most educated member may affect the productivity of these households, the schooling and employment decisions of its members, and thus their likelihood to migrate, but it does not affect the decisions of household  $i$  except through its effect on the decisions of neighboring households  $j$ .

A fifth instrument we use for the fraction of neighbors that engage in migration is the neighbors' average household average schooling, which we define as the average of the mean household schooling of other households in the village of  $i$ , but not including  $i$ , at time  $t$ . This is a good instrument because the average schooling of neighbor households  $j$  may affect the productivity of these households and thus their likelihood to migrate, but does not

affect the decisions of household  $i$  except through its effect on the decisions of neighboring households  $j$ .<sup>6</sup>

A sixth instrument we use for the fraction of neighbors that engage in migration is the neighbors' average irrigated area interacted with rain, which we define as the average irrigated land area interacted with rain of other households in the same village as  $i$ , but not including  $i$ , at time  $t$ . This is a good instrument since the average irrigated land area of neighbors  $j$  interacted with rain may affect the income generated by households  $j$  and thus their migration decisions, but does not affect the decisions of household  $i$  except through its effect on the decisions of neighboring households  $j$ .<sup>7</sup>

As we show in our results in Section 6, the first-stage F-statistic is greater than 10 in almost all specifications. To test the validity of our instruments, we also conduct an under-identification test, weak-instrument-robust inference tests, and a Sargan-Hansen test of over-identifying restrictions. In all our specifications, we reject under-identification. We also pass the Sargan-Hansen test of over-identifying restrictions in all specifications, since in each of these regressions we fail to reject the joint null hypothesis that the instruments are uncorrelated with the error term and that the excluded instruments are correctly excluded from the estimated equation.

One may worry that our instruments, which are based on characteristics of a household's neighbors, may be highly correlated with the same characteristics of the household itself. For example, if the number of males in a household does not vary much within a village, then the neighbors' average number of males in the household (one of our instruments) may be highly correlated with a household's own number of males in the household (one of our controls). However, as we show in our results in Section 6, there is variation within villages in the household characteristics on which the instruments are based so that the instruments

---

<sup>6</sup>The mean schooling in each household was constructed using the years of schooling of individuals over 15 years old.

<sup>7</sup>In their analysis of the effects of low skilled immigrants on the labor market outcomes of low skilled natives, Foged and Peri (2015) exploit the exogeneity of a Danish dispersal policy that distributed migrants from refugee counties to Denmark across municipalities to construct their instrument. Unfortunately, we do not have any similar exogenous policy in our context to exploit as an additional source of instruments.

are not too highly correlated with a household’s own control variables; and moreover the correlations between the instruments and a household’s own respective control variables are low. Thus, because the characteristics of a household are not perfectly collinear with the characteristics of its neighbors, the parameters in our endogenous effects model are identified (Manski, 1995).

To examine if the instruments are correlated with unobserved village factors that may affect migration decisions and therefore whether the exclusion restriction is satisfied, following a technique applied by Morrison and Lin Lawell (2016), we run a falsification test of the first-stage regression in which we use as dependent variables pseudo-endogenous variables rather than our actual endogenous variables. In particular, instead of the fraction of neighbors that engage in migration, we use the following pseudo-endogenous variable: the indicator variable  $y_{ikt}$  of whether household  $i$  has migration of type  $k \in [USA, Mexico]$  at time  $t$ . If the exclusion restriction is satisfied and the instruments for the fraction of neighbors that engage in migration are not correlated with unobserved village factors that affect household migration decisions, then we would expect that our instruments – the neighbors’ average number of males in household, the fraction of neighbors whose first born is male, the neighbors’ average household head school, the fraction of neighbor households in which the household head is the most educated, neighbors’ average household average schooling, and neighbors’ average irrigated area interacted with rain – should not be strong predictors of whether household  $i$  engages in migration. In other words, if the exclusion restriction is satisfied, the characteristics of neighbors  $j$  that we use as instruments should not explain the migration decisions of household  $i$ . As we show in our results in Section 6, the characteristics of neighbors  $j$  that we use as instruments do not explain the migration decisions of household  $i$ . Thus, the instruments are not correlated with unobserved village factors that affect migration decisions and the exclusion restriction is satisfied.

## 5 Data

We use data from the National Survey of Rural Households in Mexico (ENHRUM) in its three rounds (2002, 2007 and 2010<sup>8</sup>). The survey is a nationally representative sample of Mexican rural households across 80 villages and includes information on the household characteristics such as productive assets and production decisions. It also includes retrospective employment information: individuals report their job history back to 1980. With this information, we construct an annual household-level panel data set that runs from 1990 to 2010<sup>9</sup> and that includes household composition variables such as household size, household head age, and number of males in the household. For each individual, we have information on whether they are working in the same village, in some other state within Mexico (internal migration), or in the United States.

The survey also includes information about the plots of land owned by each household, including slope (flat, inclined, or very inclined), quality (good, regular, or bad), irrigation status, and land area.<sup>10</sup> We reconstruct the information for the complete panel using the date at which each plot was acquired. Since a plot's slope and quality are unlikely to change over time (unless investments were taken to considerably change the characteristics of the plots, which we do not observe very often in the data), we interact the plot variables with a measure precipitation at the village level (Jessee, Manning and Taylor, forthcoming) so the characteristics vary across households and along time. Rain data is available only for the subperiod of 1990 to 2007.

Because information on the slope and the quality of a household's plots of land is only available for the plots owned by the household, households that do not own any plots of land have missing observations for these two variables. We therefore also try estimating the

---

<sup>8</sup>The sample of 2010 is smaller than the sample of the two previous rounds because it was impossible to access some villages during that round due to violence and budget constraints.

<sup>9</sup>Since retrospective data from 1980 to 1989 included only some randomly selected individuals in each village who reported their work history, we begin our panel data set in 1990.

<sup>10</sup>We use information on plots of land which are owned by the household because our data set does not include comparable information on plots of land that are rented or borrowed.

models without using the plot-related slope and quality variables.

We use information from the National Statistics Institute (INEGI) to control for the urbanization and education infrastructure at the municipality level, including the number of basic schools and the number of indigenous schools. We also include the number of registered cars and buses. These data cover the period 1990 to 2010.

We also include aggregate variables that represent the broad state of the institutional and economic environment relevant for migration. We use data from the INEGI on the fraction of the labor force employed in each of the three productive sectors (primary, secondary, and tertiary<sup>11</sup>) at the state level, from 1995 to 2010. We use INEGI's National Survey of Employment and the methodology used in Campos-Vazquez, Hincapie and Rojas-Valdes (2012) to calculate the hourly wage at the national level from 1990 to 2010 in each of the three productive sectors and the average wage across all three sectors.

We use two sets of border crossing variables that measure the costs of migration. On the Mexican side, we use INEGI's data on crime to compute the homicide rate per 10,000 inhabitants at each of the 37 the Mexican border municipalities. On the United States' side, we use data from the Border Patrol that include the number of border patrol agents, apprehensions, and deaths of migrants at each of nine border sectors,<sup>12</sup> and match each border sector to its corresponding Mexican municipality.

We interact these border crossing variables (which are time-variant, but the same for all villages at a given point in time) with measures of distance from the villages to the border (which are time-invariant for each village, but vary for each village-border location pair).

We use a map from the International Boundary and Water Commission (2013) to obtain the location of the 26 crossing-points from Mexico to the United States. Using the Google Distance Matrix API, we obtain the shortest driving route from each of the 80 villages in

---

<sup>11</sup>The primary sector includes agriculture, livestock, forestry, hunting, and fisheries. The secondary includes the extraction industry and electricity, manufacturing, and construction. The tertiary sector includes commerce, restaurants and hotels, transportation, communication and storage, professional services, financial services, corporate services, social services, and government and international organizations.

<sup>12</sup>A "border sector" is the term the Border Patrol uses to delineate regions along the border for their administrative purposes.

the sample to each of the 26 crossing-points, and match the corresponding municipality at which these crossing-points are located. This procedure allows us to categorize the border municipalities into those less than 1,000 kilometers from the village; and those between 1,000 and 2,000 kilometers from the village.

By interacting the distances to the border crossing points with the border crossing variables, we obtain the mean of each border crossing variable at each of the three closest crossing points, and the mean of each border crossing variable within the municipalities that are in each of the two distance categories defined above. We also compute the mean of each border crossing variable among all the border municipalities.

Figure 1 presents a map of the villages in our sample (denoted with a filled black circle) and the US-Mexico border crossing points (denoted with a red X).

Table 1 presents the summary statistics for the variables in our data set. Table 2 presents the within and between variation for the migration variables. 'Within' variation is the variation in the migration variable across years for a given village. 'Between' variation is the variation in the migration variable across villages for a given year.

## 6 Results

In this section we present the results of the reduced-form models we run to analyze the effects of neighborhood effects on a household's decisions regarding migration. We run two sets of regressions: one for the decision to migrate to the US, and the other for the decision to migrate within Mexico. The parameters of interest are the coefficient on the fraction of households in the same village as household  $i$ , excluding  $i$ , with migration to the US; and the coefficient on the fraction of households in the same village as  $i$ , excluding  $i$ , with migration within Mexico.

## 6.1 Validity of the instruments

Table 3 presents the results of our first-stage regressions.<sup>13</sup> The first stage F-statistic is greater than 10 in almost all specifications. To test the validity of our instruments, we also conduct an under-identification test, weak-instrument-robust inference tests, and a Sargan-Hansen test of over-identifying restrictions. In all our specifications, we reject under-identification. We also pass the Sargan-Hansen test of over-identifying restrictions in all specifications, since in each of these regressions we fail to reject the joint null hypothesis that the instruments are uncorrelated with the error term and that the excluded instruments are correctly excluded from the estimated equation.

One may worry that our instruments, which are based on characteristics of a household's neighbors, may be highly correlated with the same characteristics of the household itself. For example, if the number of males in a household does not vary much within a village, then the neighbors' average number of males in the household (one of our instruments) may be highly correlated with a household's own number of males in the household (one of our controls).

To address this concern and provide further evidence supporting the exclusion restriction, we examine the variation within villages in the values of household characteristics on which the instruments are based. For each village-year, we calculate the mean and standard deviation of the household characteristics on which the instruments are based across all households in that village-year. Panels A and B of Table 4 present summary statistics of the mean and standard deviation, respectively, over village-years of the household characteristics in each village-year. We then divide the mean standard deviation by the mean mean; the summary statistics for the ratio of the standard deviation over the mean over village-years are presented in Panel C of Table 4.

As seen in Panel C of Table 4, we find that the ratio of the mean standard deviation over

---

<sup>13</sup>The results of the first-stage regressions for all the US and within-Mexico migration specifications are available from the authors upon request.

the mean mean is non-zero for all of the covariates on which the instruments are based. For example, for irrigated area interacted with rain, the ratio of the mean (over village-years) of the standard deviation within a village-year, over the mean (over village-years) of the mean within a village-year is 2.46, which provides evidence that there is considerable variation in irrigated area interacted with rain within a village-year, and therefore that the neighbors' average irrigated area interacted with rain (one of our instruments) is not highly correlated with a household's own irrigated area interacted with rain (one of our controls). Thus, there is variation within villages in the household characteristics on which the instruments are based so that the instruments are not too highly correlated with a household's own respective control variables.

To provide further evidence that the instruments are not too highly correlated with a household's own respective control variables, we calculate the correlations between each instrument measuring neighbors' characteristics and its respective own household characteristic. As seen in Table 5, the correlations between the instruments and their corresponding own variables are low.

Thus, because the characteristics of a household are not perfectly collinear with the characteristics of its neighbors, the parameters in our endogenous effects model are identified (Manski, 1995).

To examine if the instruments are correlated with unobserved village factors that may affect migration decisions and therefore whether the exclusion restriction is satisfied, following a technique applied by Morrison and Lin Lawell (2016), we run a falsification test of the first-stage regression in which we use as dependent variables pseudo-endogenous variables rather than our actual endogenous variables. In particular, instead of the fraction of neighbors that engage in migration, we use the following pseudo-endogenous variable: the indicator variable  $y_{ikt}$  of whether household  $i$  has migration of type  $k \in [USA, Mexico]$  at time  $t$ . If the exclusion restriction is satisfied and the instruments for the fraction of neighbors that engage in migration are not correlated with unobserved village factors that affect

household migration decisions, then we would expect that our instruments – the neighbors’ average number of males in household, the fraction of neighbors whose first born is male, the neighbors’ average household head school, the fraction of neighbor households in which the household head is the most educated, neighbors’ average household average schooling, and neighbors’ average irrigated area interacted with rain – should not be strong predictors of whether household  $i$  engages in migration. In other words, if the exclusion restriction is satisfied, the characteristics of neighbors  $j$  that we use as instruments should not explain the migration decisions of household  $i$ .

We present the results of our falsification test of the first-stage regressions in Table 6. The first-stage F-statistics are all much lower than 10. The characteristics of neighbors  $j$  that we use as instruments therefore do not explain the migration decisions of household  $i$ . Thus, the instruments are not correlated with unobserved village factors that affect migration decisions and the exclusion restriction is satisfied.

## 6.2 Neighborhood Effects

Tables 7 and 8 present the main results of our paper for migration to the US and migration within Mexico, respectively. For each specification in Tables 7 and 8, version ‘a’ of the specification includes year effects, while version ‘b’ uses a time trend instead. Specification 1a is our base case specification. Specification 2 excludes the plot-related variables (which are interacted with rain), so the sample size increases. Specification 3 is analogous to the base case but instead of using a variable for the household head schooling, we use a dummy for the household head being the household member with the most schooling.

According to the results for the US migration regressions in Table 7, there is a positive and significant own-migration neighborhood effect that is robust across specifications. In the base case specification 1a, an increase of 0.1 in the fraction of neighbors with migration to the US increases a household’s probability of migration to the US by 5.86 percentage points. The result is robust across specifications; an increase of 0.1 in the fraction of neighbors with

migration to the US increase a household's probability of migration to the US by 4.3 to 7.7 percentage points in the specifications that include year effects (1a, 2a, and 3a), and by 5.8 to 6.7 percentage points in the specifications that include a time trend instead (1b, 2b, and 3b). Additionally, the other-migration neighborhood effect is negative and significant at a 5% level in some specifications: there is some evidence that the fraction of neighbors with migration within Mexico has a negative effect on a household's probability of migration to the US.

Table 8 presents the results for the migration to other states within Mexico. Once again, there is a positive and significant own-migration neighborhood effect that is robust across specifications. In the base case specification 1a, an increase of 0.1 in the fraction of neighbors with migration to other states within Mexico increases a household's probability of migration to other states within Mexico by 6.33 percentage points. The result is robust across specifications; an increase of 0.1 in the fraction of neighbors with migration to other states within Mexico increases a household's probability of migration to other states in Mexico by 5.6 to 6.3 percentage points in the specifications that include year effects (1a, 2a, and 3a), and by 4.1 to 6.1 percentage points in the specifications that include a time trend instead (1b, 2b, and 3b). In contrast, the other-migration neighborhood effect is not significant at a 5% level: the fraction of neighbors with migration to the US has no significant effect on a household's probability of migration to other states within Mexico.

### 6.3 Other Determinants of Migration

Table 7 also presents the results of other characteristics that may explain migration to the US. The number of indigenous schools has a positive effect on migration to the US that is significant in some specifications.<sup>14</sup> The number of males in the household has a positive effect that is significant in all specifications, which is consistent with the previous literature

---

<sup>14</sup>In addition, the number of basic schools has a significant negative effect in specification 3a, but its coefficient is lower in magnitude than that of the significant positive coefficient on the number of indigenous schools.

on the determinants of migration, which finds that migrants from Mexico to the US are more likely to be male than female. The household head age has a significant positive effect in all specifications.

Household head schooling and whether the household head is the most educated both have a significant negative effect on the probability of migration to the US, which could provide evidence in favor of the negative selection hypothesis. Similarly, household average schooling has a negative effect that is significant in some specifications. However, the household's maximum level of schooling has a significant positive effect on the probability of migration to the US. Thus, while the household maximum schooling increases the probability of migration to the US, having the household head be the one with the most education in the household and having a high household average schooling decrease the probability of migration to US.

To control for persistence in migration, we include the lag of the fractions of household members migrating to the US and within Mexico, respectively, as regressors. The lagged fraction of household members migrating to the US has a significant positive effect on the probability of migration to the US. The lagged fraction of household members migrating to other states within Mexico has positive effect on the probability of migration to the US that is smaller in magnitude and significant in some specifications.

Table 8 also presents the results of other characteristics that may explain migration to other states within Mexico. The number of males in the household has a significant positive effect on migration to other states within Mexico. The age of the household head has a significant positive effect on the probability of migrating within Mexico. Whether the first born in the household is a male has a significant negative effect in some specifications.

Household head schooling and whether the household head is the most educated in household both have a significant negative effect on the probability of migrating within Mexico. Household maximum schooling has a significant positive effect in some specifications. Thus, while the household maximum schooling increases the probability of migration within Mexico, having the household head be the one with the most education in the household decreases

the probability of migration within Mexico.

The lagged fraction of household members migrating within Mexico has a significant positive effect on the probability of migration within Mexico, which provides evidence for a high degree of persistence. In contrast, the lagged fraction of household members migrating to the US has no significant effect on the probability of migration within Mexico.

## 6.4 Robustness

We examine the robustness of our results by running alternative specifications that are variants of the base case specification 1a from Tables 7 and 8 for migration to the US and migration within Mexico, respectively. The results of our robustness checks are in Tables 9 and 10 for migration to the US and within Mexico, respectively. Specification 4 includes employment in the primary sector; and hourly wages in the primary, secondary, and tertiary sectors as additional regressors. Specifications 5-9 uses employment in the tertiary sector instead of employment in the primary sector, and the mean hourly wage instead of the hourly wages in the primary, secondary, and tertiary sectors. In addition, specifications 5-8 vary which measures of the border crossing variables are used. Specification 9 normalizes the municipality characteristics using the municipality population, and normalizes the border enforcement variables using the length of the border that each border municipality shares with the US.

The first stage F-statistic is greater than 10 in almost all specifications. In all the specifications of the corresponding first stage, we reject under-identification. We also pass the Sargan-Hansen test of over-identifying restrictions in all specifications, since in each of these regressions we fail to reject joint null hypothesis that the instruments are uncorrelated with the error term and that the excluded instruments are correctly excluded from the estimated equation.<sup>15</sup>

The main results from our base case specification are robust to changes in the wage, em-

---

<sup>15</sup>The results of the first-stage regressions for all the US and within-Mexico migration specifications are available from the authors upon request.

ployment, and border crossing variables. In the US migration results in Table 9, an increase in the fraction of neighbors with migrants to the US increases a household's probability of migration by 5.1 to 7.2 percentage points. In addition, the number of males in the household, the household head age, the maximum level of schooling in the household, the number of indigenous schools, the lagged fraction of household members with migration to the US, and the lagged fraction of household members with migration within Mexico have significant positive effects on the probability of having a migrant to the US. The fraction of neighbors with migration within Mexico, the number of basic schools, household head schooling, and household average schooling have significant negative effects on the probability of having a household member migrate to the US.

In Figure 2 we summarize our findings on the own-migration neighborhood effect for migration to the US across specifications 1a-3a of Table 7 and specifications 4-9 of Table 9.

Similarly, Table 10 shows that the main results from our base case specification for the Mexico migration analysis are robust to changes in the wage, employment, and border crossing variables as well. In the robustness checks, an increase in the fraction of neighbors with migrants within Mexico increases a household's probability of migration by 5.5 to 8.9 percentage points. The schooling of the household head has a negative effect on the probability of migration but the maximum level of any of the household members has a positive effect. The number of males in the household, the household head age, lagged fraction of household members with migration within Mexico, and the number of deaths at the closest border crossing point to the US have a significant positive effect on the probability of migration to other states within Mexico. The fraction of neighbors with migrants to the US, the lagged fraction of household members with migration to the US, and the average number of apprehensions at the closest border crossing point to the US has a significant negative effect on effect on the probability of migration to other states within Mexico in some specifications.

In Figure 3 we summarize the findings of our results on the own-migration neighborhood

effect for migration within Mexico across specifications 1a-3a of Table 8 and specifications 4-9 of Table 10.

## 6.5 Results by Village Size

It is possible that differences in the sizes of the host economies might affect the extent of the neighborhood effects. The reason is that the size of the village might affect how well the information is spread, how reliable the information is, the costs of information sharing, and possibly also the (perceived or actual) competition effect. Furthermore, the relationship between village size and the extent of the neighborhood effects might not be linear or monotonically increasing.

A possible reason why the neighborhood effects may vary non-linearly with village size is that the information externalities may vary with village size. The spread of information and information spillovers may be facilitated in small and medium-size communities, where people tend to know each other, and where actions of other households are easily inferred or observed. Neighborhood effects may be less important in big communities where there may be less face-to-face interaction, which may decrease the value of the information.

Another possible explanation why the neighborhood effects may vary non-linearly with village size is that competition effects may vary with village size. In small and medium-size villages, individuals may not perceive others to be competing with them for jobs in the United States. However, as the village size grows, individuals may perceive that a bigger pool of migrants might affect their chances of getting a job. We hypothesize that competition effects are less likely to explain neighborhood effects in migration decisions to the US, however, since the labor market in the US is large relative to the number of migrants from a particular village.

To formally analyze the relationship between village size and the neighborhood effects, we interact the fraction of neighbors with migration to US and the fraction of neighbors with migration within Mexico with village size quartile dummies based on the village size in 1990.

We similarly interact the instruments with village size quartile dummies as well.

In all the specifications of the first-stage analysis by village size, we reject under-identification. We also pass the Sargan-Hansen test of over-identifying restrictions in all specifications, since in each of these regressions we fail to reject joint null hypothesis that the instruments are uncorrelated with the error term and that the excluded instruments are correctly excluded from the estimated equation.<sup>16</sup>

Table A.1 in the Appendix presents the results of the village size analysis for US migration. Specification 10a is analogous to the base case specification 1a of Table 7 whereas specification 11a is analogous to specification 2a of the same table. Specifications 10b and 11b use time trends instead of year effects. The results are robust and show a positive coefficient on the fraction of neighbors with migrants to the US for the first village size quartile (i.e., the small villages) that is only significant at a 10% level; a positive coefficient on the fraction of neighbors with migrants to the US that is significant at a 5% level for the second and third village size quartiles (i.e., the medium-size villages); and a negative coefficient on the fraction of neighbors with migrants to the US that is not significant on the fourth village size quartile (i.e., the large villages). The magnitude of the own-migration neighborhood effect in village size quartiles 2 and 3 are in line with those in Table 7. The own-migration neighborhood effect in village size quartile 1 (the small villages) is smaller in magnitude and only significant at a 10% level. Figure 4 presents a graphical summary of the results. For the other-migration neighborhood effect, we find that, in the third village size quartile, the fraction of neighbors with migration within Mexico has a significant negative effect on a household's decision to engage in migration to the US.

Table A.2 in the Appendix presents the same analysis for the migration within Mexico. There is a significant positive own-migration neighborhood effect in the first quartile (i.e., the small villages), but only in specifications 10a and 10b. There is a positive own-migration neighborhood effect in the third quartile, but it is only significant at a 10% level in all but

---

<sup>16</sup>The results of the first-stage regressions for all the US and within-Mexico migration specifications are available from the authors upon request.

specification 11b. Figure 5 summarizes the findings in Table A.2.

## 6.6 Nonlinearities in the Neighborhood Effect

The previous analysis provides strong evidence that strategic considerations are important in shaping the probabilities that a household has migrants to the US and/or within Mexico. We also find that the neighborhood effects depend on village size. Another type of nonlinearity in the neighborhood effects may also be present: the effect of the fraction of neighbor households with migration on a household's migration decision may be a nonlinear function of the fraction of neighbor households with migrants.

To formally test for nonlinearities in the neighborhood effect in the most flexible way, we estimate a semiparametric partially linear IV model using Robinson's (1988) double residual estimator to semi-parametrically identify non-linearities in the own-migration neighborhood effect. We use a two-step procedure to account for the endogeneity of the strategic variables with a control function approach (Verardi, 2013). In the first stage, we fit two panel fixed effects models regressing the fraction of households with migrants to the US and within Mexico, respectively, on the same instruments and controls as we used in our base case specification 1a from Tables 7 and 8 respectively, and estimate the residuals. In the second stage, we run a semi-parametric estimation where the dependent variable is the migration dummy, controlling for the same controls as in our base case specification 1a, and adding the first-stage residuals as additional regressors. The controls, the residual estimated in the first stage, and village and year fixed effects are estimated parametrically, while the endogenous regressor – the fraction of households engaged in migration to the US (within Mexico) – is allowed to vary non-parametrically.

To examine any nonlinearities in the own-migration neighborhood effect for migration to the US, Figure 6 plots the partialled-out residual in the analysis of the decision to migrate to the US as a function of the fraction of neighbors with migration to the US. In general we seem to find a linear effect.

Similarly, to examine any nonlinearities in the own-migration neighborhood effect for migration within Mexico, Figure 7 plots the partialled-out residual in the analysis of the decision to migrate within Mexico as a function of the fraction of neighbors with migration to within Mexico. The relationship again seems to be linear.

We also run two additional alternative specifications of the semiparametric partially linear IV model. In one alternative specification, we run the semiparametric partially linear IV model without instrumenting for the other-migration neighborhood effect. In the other alternative specification, we run the semiparametric partially linear IV model without including the other-migration neighborhood effect as a regressor. Our results are robust across all specifications. Thus, our test for nonlinearities in the migration neighborhood effects do not reject the hypothesis that the neighborhood effects are linear in the fraction of neighbor households with migrants.

## 7 Conclusion

We contribute to the literature on the determinants of migration by examining whether neighborhood effects matter for migration decisions. There are several reasons why a household's migration decisions may depend on the migration decisions of its neighbors, including migration networks and information externalities. Using instrumental variables to address the endogeneity of neighbors' decisions, we empirically examine whether neighborhood effects in migration decisions actually take place in rural Mexico, whether the interactions depend on the size of the village, and whether there are nonlinearities in the neighborhood effects.

Our results show that there is a significant and positive own-migration neighborhood effect. In our base case specification, an increase of 0.1 in the fraction of neighbors with migration to the US increases a household's probability of migration to the US by around 5.9 percentage points, while an increase of 0.1 in the fraction of neighbors with migration to

other states within Mexico increases a household's probability of migration to other states within Mexico by around 6.3 percentage points.

We study the relationship between the extent of the neighborhood effects and village size, and find evidence that the neighborhood effects vary by village size, likely because the information externalities vary with village size. For the case of migration to the United States, we find that neighborhood effects occur in villages in village size quartiles 2 and 3 (the medium-size villages), while they are not significant at a 5% level in villages of village size quartiles 1 and 4. Thus, neighborhood effects appear to be concave in village size, which is consistent with Wahba and Zenou (2005), who show that, conditional on being employed, the probability of finding a job through social networks, relative to other search methods, increases and is concave with the size of the network.

On the other hand, in the case of migration to other states within Mexico, results show that the neighborhood effects take place in villages in village size quartile 1 (the smallest villages), and are only significant at a 10% level in village size quartile 3. These results, together with the differences in magnitudes of the estimated coefficients, imply that the strategic motivations behind international and domestic migration are different.

Our results therefore suggest that neighborhood effects among households in a village have an important role in household migration decisions that has been heretofore neglected in the literature.

There are several potential avenues for future research. First, the analysis in this paper was based on reduced-form regressions of migration. In Rojas Valdes, Lin Lawell and Taylor (2017a,b), we further analyze neighborhood effects in migration by developing and estimating a structural econometric model of the dynamic game between households deciding whether or not to engage in migration to the US and within Mexico.

Second, our empirical model is general enough to capture multiple possible sources of neighborhood effects, including migration networks, information externalities, relative deprivation, risk sharing, and competition effects, and enables us to analyze their net effect. In

future work we hope to further distinguish among different possible sources of neighborhood effects.

Figure 1: Location of sampled villages in the ENHRUM survey and the border crossing municipalities

Table 1: Summary statistics

Variable	Mean	Std.Dev.	Min	Max	# Obs
Household migration variables					
Household has a migrant to the US (dummy)	0.17	0.38	0	1	25761
Household has a migrant within Mexico (dummy)	0.2	0.4	0	1	25761
Neighbor migration variables					
Fraction of neighbors with migrants to US	0.17	0.21	0	1	25761
Fraction of neighbors with migrants to Mexico	0.2	0.17	0	0.89	25761
Household characteristics					
Number of household members	5.94	3.15	1	24	25761
Number of family members	5.48	2.83	1	17	25761
Number of children in household	2.17	1.86	0	12	25761
Number of children in family	1.82	1.85	0	11	25761
Number of males in household	2.93	1.84	0	17	25761
Number of males in family	2.74	1.72	0	12	25761
First born is a male (dummy)	0.5	0.5	0	1	25761
Household head age (years)	45.15	16.26	3	100	25725
Household head schooling (years)	4.75	3.84	0	23	25725
Household average schooling (years)	6.21	2.97	0	20.5	25554
Household maximum schooling (years)	8.99	3.84	0	23	25761
Household head is the most educated (dummy)	0.26	0.44	0	1	30313
Irrigated area (hectares)	0.22	3.38	0	426	21257
Plots' slope (1 = flat)	3.42	0.81	1	4	23836
Plots' quality (1 = good)	3.33	0.92	1	4	23811

Table 1: (continued)

Variable	Mean	Std.Dev.	Min	Max	# Obs
Municipality characteristics					
Number of basic schools	284.97	332.44	0	1762	22763
Number of indigenous schools	6.08	12.78	0	72	23313
Number of schools	238.87	301.17	0	1603	13107
Number of classrooms	1399.33	2236.64	0	12707	13322
Number of public libraries	20.09	34.74	0	327	11523
Number of labs	47.84	82.72	0	482	12987
Number of workshops	42.78	69.6	0	424	12987
Number of public libraries	4.92	5.69	0	28	19165
Number of students	42284.31	70057.57	0	372625	22763
Number of vehicles	44556.99	88624.85	0	502836	24220
Number of cars	29396.74	64269.9	0	383512	24220
Number of buses	371.1	841.11	0	5355	24220
Number of trucks	14203.43	23759.15	0	113819	24220
Number of motos	585.72	1685.87	0	18650	24220
Instruments					
Neighbors' average number of males in household	2.93	0.7	1.32	7.2	25761
Fraction of neighbors whose first born is male	0.5	0.13	0	1	25761
Neighbors' average household head schooling (years)	4.75	1.52	0.75	11.67	25725
Fraction of neighbors w/ household head the most educated	0.26	0.15	0	0.73	30313
Neighbors' average household average schooling (years)	6.07	1.61	1.81	12.17	25243
Neighbors' average irrigated area interacted with rain	77.44	281.02	0	4307.88	16735
State-level variables					
Employment in primary sector (% working population)	20.3	10.37	4.3	52	20635
Employment in secondary sector (% working population)	26.58	6.03	15.1	40.7	20635
Employment in tertiary sector (% working population)	52.78	7.14	31.6	68.1	20635

Table 1: (continued)

Variable	Mean	Std.Dev.	Min	Max	# Obs
National variables					
Hourly wage in primary sector	29.48	5.3	21.91	39.45	30313
Hourly wage in secondary sector	31.77	3.4	24.9	35.98	30313
Hourly wage in tertiary sector	37.81	4.21	30.27	43.54	30313
Average hourly wage	35.97	3.34	29.61	41.44	33873
Border crossing variables					
Distance to the closest border crossing point (km)	847.4	474.1	7.0	2178.3	30352
Number of border crossing points					
... < 1000 km	6.3	5.4	0.0	17.0	30352
... 1000-2000 km	12.4	6.0	0.0	26.0	30352
Average crime rate (murders per 10,000 inhabitants)					
... in crossing municipalities < 1000 km	11.5	8.8	1.9	83.7	12166
... in crossing municipalities 1000-2000 km	12.2	7.4	2.9	52.3	16612
... along border municipalities	14.3	2.5	9.9	18.4	17554
... at the closest crossing point	8.7	6.6	0.0	38.2	17554
... at the second closest crossing point	13.8	26.3	0.0	217.4	17554
... at the third closest crossing point	9.6	19.2	0.0	144.2	17554
Average number of apprehensions					
... in crossing municipalities < 1000 km	139460.2	77498.3	44895.0	616346.0	21018
... in crossing municipalities 1000-2000 km	117863.6	52672.6	9964.9	359035.0	28716

Table 2: Within and between variation of migration decisions

		Mean	Std. Dev.	Min	Max	# Obs
Household has a migrant to the US (dummy)						
	Overall	0.1746	0.3796	0.0000	1.0000	25,761
	Within		0.2254	-0.7778	1.1269	
	Between		0.3095	0.0000	1.0000	
Household has a migrant within Mexico (dummy)						
	Overall	0.2000	0.4000	0.0000	1.0000	25,761
	Within		0.2477	-0.7523	1.1524	
	Between		0.3197	0.0000	1.0000	

Notes: Within variation is the variation in the migration variable across years for a given village. Between variation is the variation in the migration variable across villages for a given year.
